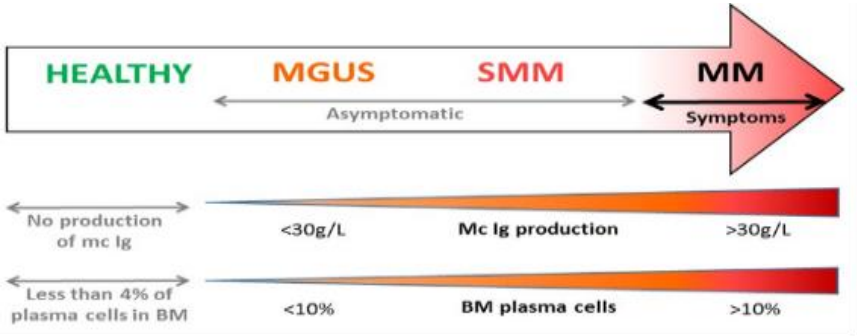
FRANCE

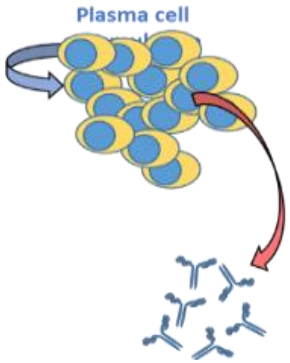
Monoclonal Gammopathies

Three stages: 1. Monoclonal Gammopathy of Undetermined Significance = MGUS

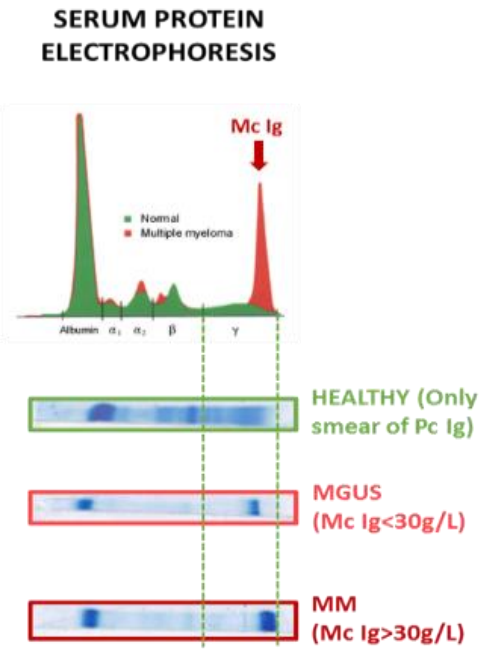
2. Smoldering Multiple Myeloma = SMM

3. Multiple Myeloma = MM





The targets of Mc Igs are rarely studied



Disease may progress from the asymptomatic MGUS stage toward SMM, then toward overt MM.

MGUS, SMM and MYELOMA

Prevalence

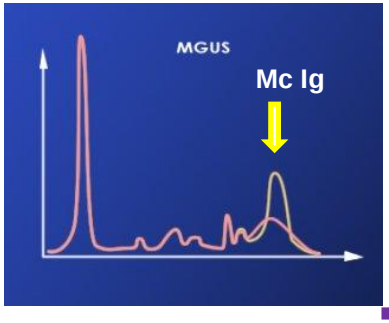
France
≈ 900 000 MGUS
(40 000 new cases/year)
≈ 100 000 Myeloma

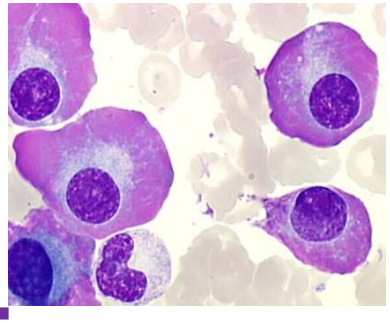
Europe
≈ 5.5 millions MGUS

≈ 600 000 Myeloma

MGUS / SMM

≈ 3-5% population after age 50
Monoclonal Immunoglobulin (Mc Ig) < 30 g/L
Plasma cells < 10% in bone marrow
No symptoms, No treatment – **Monitoring of Mc Ig**





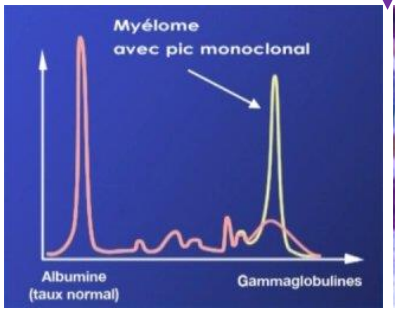
Evolution MGUS -> SMM -> Myeloma

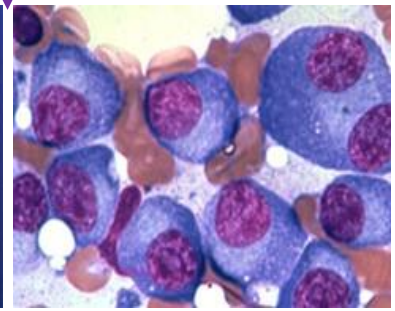
Slow: > 10 ans
Markers of progression: few, and weakly predictive
+1%/year/patient (= 15% in 10 years, 30% in 20 years)

Myeloma

Mc Ig > 30 g/L, Plasma cells > 10% in bone marrow

Symptoms: "CRAB"
Calcemia
Renal insufficiency
Anemia
Bone lesions





Myeloma Treatment: Intensive therapy aimed at suppressing the plasmacytic clone

Median survival: 6 years

Rationale for a New Approach to MGUS and MM

- ✓ Treaments are rarely curative as long as the cause(s) of a disease is/are not known

  ➡ **Try to find (a) cause(s) for MGUS and MM**

- ✓ The patient's Mc Ig is a major marker of MGUS and MM disease: **yet Mc Ig were assumed not to have antibody function, and were not studied**

Our Rationale

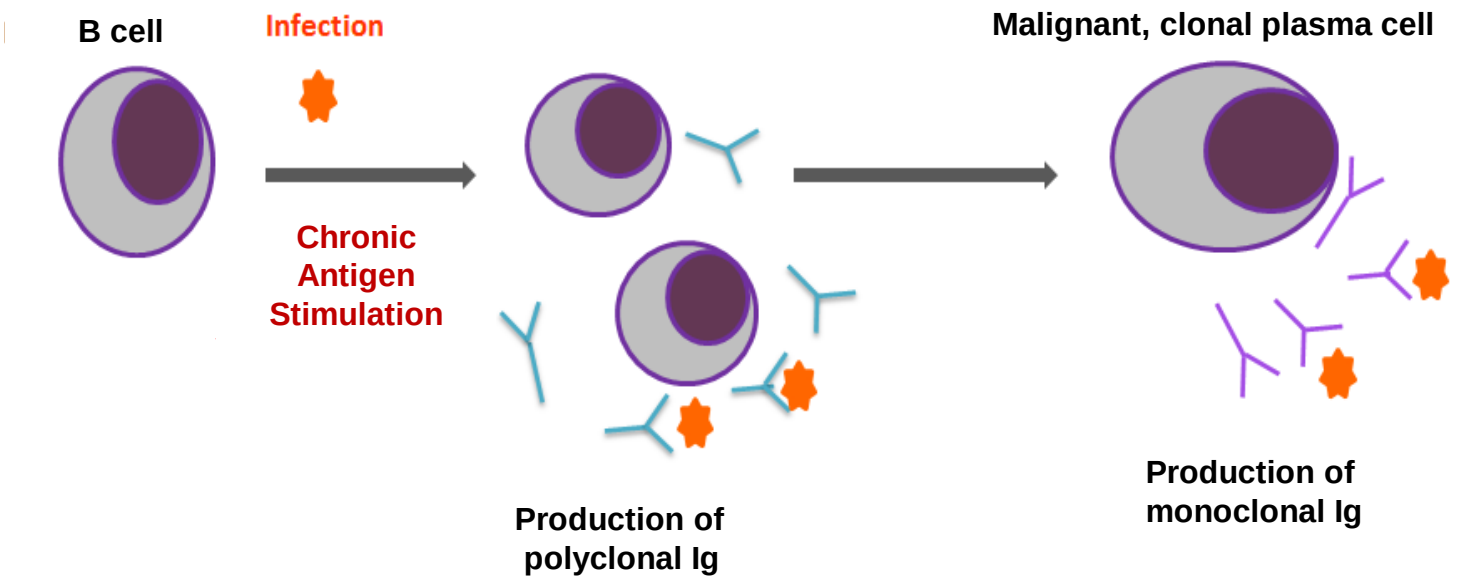
- ✓ **Ig are typically produced to fight infections**
- ✓ Chronic infection at the MGUS stage would explain the inflammation observed in MGUS

  ➡ ***For subsets of patients, Mc Ig may target antigens from infectious pathogens***

  ➡ ***New assay to determine whether a Mc Ig targets an infectious pathogen or protein***

Infectious Origin of Monoclonal Gammopathies?

- ✓ Latent infection could explain inflammation at the MGUS stage
- ✓ An abnormal Ig response to infectious pathogen may lead to MGUS (poly-, oligo-, then monoclonal Ig)
- ✓ Accumulation of genetic alterations in clonal plasma cells eventually lead to SMM then Myeloma



- ✓ Knowing the target of the Mc Ig would indicate the **initial event of the clonal gammopathy**
- ✓ **Novel therapeutic approach: Treat the target of the Monoclonal Ig** to reduce or suppress antigen-induced stimulation of clonal plasma cells and Mc Ig production, hereby preventing evolution toward myeloma

Example: Mc Ig from HCV-infected Patients Typically Recognize a HCV protein

Hermouet et al. New Engl J Med 2003 **(1 case)**

Hepatitis C Virus, Human Herpesvirus 8, and the Development of Plasma-Cell Leukemia

TO THE EDITOR: The role of hepatitis C virus (HCV) and human herpesvirus 8 (HHV-8), two B-cell–tropic viruses, in B-cell proliferation[1] is illustrated by the following unusual case of plasma-cell leukemia. In 1995, a 32-year-old man with a history of hepatitis A virus and HCV infection but who tested negative for hepatitis B virus and human immunodeficiency virus was admitted to the hospital with septic shock, bilateral pneumonia, and hepatosplenomegaly. The hemoglobin level was 8.9 g per deciliter; the white-cell count was 26.6×10^9 per liter with 50 percent plasmablasts (Fig. 1A), 41 percent neutrophils, 7 percent lymphocytes, and 2 percent monocytes; the platelet count was 99×10^9 per liter. ed in tumor cells of an HCV-positive patient with primary-effusion lymphoma, a condition associated with HHV-8.[4]

Retrospective studies were consistent with an HCV-driven process leading to plasma-cell leukemia. Immunoblotting showed that the monoclonal IgG kappa was directed against HCV core protein (Fig. 1B). The patient had HCV viremia (type 1a) and HHV-8 viremia (subtype C'). Reverse-transcriptase polymerase-chain-reaction (PCR) and immunofluorescence studies revealed that his plasmablasts were infected by HCV and produced HCV core protein (Fig. 1C). Immunofluorescence and real-time (TaqMan) quantitative PCR studies indi-

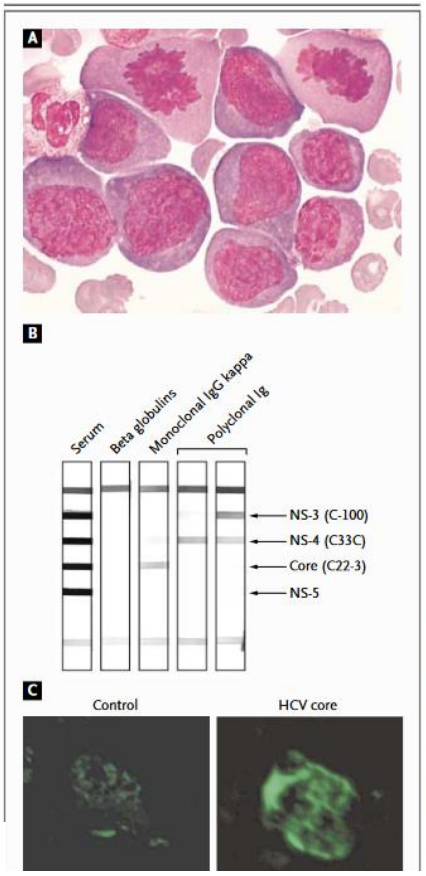


Figure 1. Studies in a Patient with Plasma-Cell Leukemia.

Panel A shows May–Grunwald–Giemsa staining of blood plasmablasts (×100). Abnormal cells exhibited a plasmablastic morphology: a large nucleus with an irregular shape; fine, homogeneous chromatin and prominent nuclei; reduced cytoplasm with little or no perinuclear hof. Mitotic figures were frequent. Panel B shows the specificity of monoclonal IgG kappa for the hepatitis C virus (HCV) core protein. The patient's serum monoclonal IgG kappa was separated by charge from polyclonal immunoglobulin (Ig) and beta globulins on an agarose gel (Paragon SPE-II, Beckman Coulter). Parts of the gel corresponding to each protein fraction were carefully cut, and proteins were eluted. The purity of each protein fraction was confirmed by immunofixation analysis (Titan Immunogel, Helena Biosciences), and then purified immunoglobulin was subjected to a recombinant immunoblot assay (RIBA III, Ortho Diagnostic Systems), which detects immunoglobulin directed against fragments of the HCV nonstructural proteins NS-3, NS-4, and NS-5 and fragment C22-3 of the core protein. Two purified polyclonal immunoglobulin fractions recognized HCV NS-3 and NS-4 proteins. The monoclonal IgG kappa fraction recognized HCV core protein; it also weakly recognized NS-4, most likely because of overlap with one polyclonal immunoglobulin fraction. The beta globulin fraction, used as a negative control, did not recognize HCV peptides. Panels C and D show immunofluorescence studies. Plasmablasts were incubated with a primary antibody — a control antibody or an antibody specific for HCV core protein (Affinity Bioreagents) or specific for the human herpesvirus 8 (HHV-8) productive phase ORF 59 or ORF K8.1 (Advanced Biotechnologies) — and then with a secondary antibody labeled with fluorescein isothiocyanate. Images show the perinuclear, globular fluorescence characteristic of HCV. Magnification was ×100 for HCV and ×40 for HHV-8.

Chronic Inflammation in MGUS and in Myeloma

Analysis of inflammation in the serum of MGUS and Myeloma patients:

- ✓ Cytokine profiles of 148 patients (68 MGUS, 6 SMM, 74 MM)
- ✓ 40 cytokines quantified using the Luminex technology (Bio-Plex 200, Bio-Rad)
- ✓ **Serum levels of 36/40 cytokines were similarly elevated in MGUS and in MM**

  Only HGF, IL-11, SDF-1α and RANTES were significantly higher in MM than in MGUS

Monoclonal IgG in MGUS and multiple myeloma targets infectious pathogens

Adrien Bosseboeuf,[1] Delphine Feron,[1] Anne Tallet,[2] Cédric Rossi,[2] Cathy Charlier,[4] Laurent Garderet,[4,67] Denis Caillot,[5] Philippe Moreau,[6] Marina Cardó-Vila,[8,10] Renata Pasqualini,[8,10] Wadih Arap,[10,11] Alfreda Destea Nelson,[10,12] Bridget S. Wilson,[10,12] Hélène Perreault,[13] Eric Piver,[2,14] Pierre Weigel,[4] François Girodon,[15] Jean Harb,[16,17] Edith Bigot-Corbel,[1,17] and Sylvie Hermouet[1,18]

Subsets of mature B cell neoplasms are linked to infection with intracellular pathogens such as Epstein-Barr virus (EBV), hepatitis C virus (HCV), or *Helicobacter pylori*. However, the association between infection and the immunoglobulin-secreting (Ig-secreting) B proliferative disorders remains largely unresolved. We investigated whether the monoclonal IgG (mc IgG) produced by patients diagnosed with monoclonal gammopathy of undetermined significance (MGUS) or multiple myeloma (MM) targets infectious pathogens. Antigen specificity of purified mc IgG from a large patient cohort (n = 244) was determined using a multiplex infectious-antigen array (MIAA), which screens for reactivity to purified antigens or lysates from 9 pathogens. Purified mc IgG from 23.4% of patients (57 of 244) specifically recognized 1 pathogen in the MIAA. EBV was the most frequent target (15.6%), with 36 of 38 mc IgGs recognizing EBV nuclear antigen-1 (EBNA-1). MM patients with EBNA-1–specific mc IgG (14.0%) showed substantially greater bone marrow plasma cell infiltration and higher β_2-microglobulin and inflammation/infection-linked cytokine levels compared with other smoldering myeloma/MM patients. Five other pathogens were the targets of mc IgG: herpes virus simplex-1 (2.9%), varicella zoster virus (1.6%), cytomegalovirus (0.8%), hepatitis C virus (1.2%), and *H. pylori* (1.2%). We conclude that a dysregulated immune response to infection may underlie disease onset and/or progression of MGUS and MM for subsets of patients.

Hepatitis C Virus, Human Herpesvirus 8, and the Development of Plasma-Cell Leukemia

TO THE EDITOR: The role of hepatitis C virus (HCV) and human herpesvirus 8 (HHV-8), two B-cell–tropic viruses, in B-cell proliferation[1] is illustrated by the following unusual case of plasma-cell leukemia. In 1995, a 32-year-old man with a history of hepatitis A virus and HCV infection but who tested negative for hepatitis B virus and human immunodeficiency virus was admitted to the hospital with septic shock, bilateral pneumonia, and hepatosplenomegaly. The hemoglobin level was 8.9 g per deciliter; the white-cell count was 26.6×10^9 per liter with 50 percent plasmablasts (Fig. 1A), 41 percent neutrophils, 7 percent lymphocytes, and 2 percent monocytes; the platelet count was 99×10^9 per liter. ed in tumor cells of an HCV-positive patient with primary-effusion lymphoma, a condition associated with HHV-8.[4]

Retrospective studies were consistent with an HCV-driven process leading to plasma-cell leukemia. Immunoblotting showed that the monoclonal IgG kappa was directed against HCV core protein (Fig. 1B). The patient had HCV viremia (type 1a) and HHV-8 viremia (subtype C'). Reverse-transcriptase polymerase-chain-reaction (PCR) and immunofluorescence studies revealed that his plasmablasts were infected by HCV and produced HCV core protein (Fig. 1C). Immunofluorescence and real-time (TaqMan) quantitative PCR studies indi-

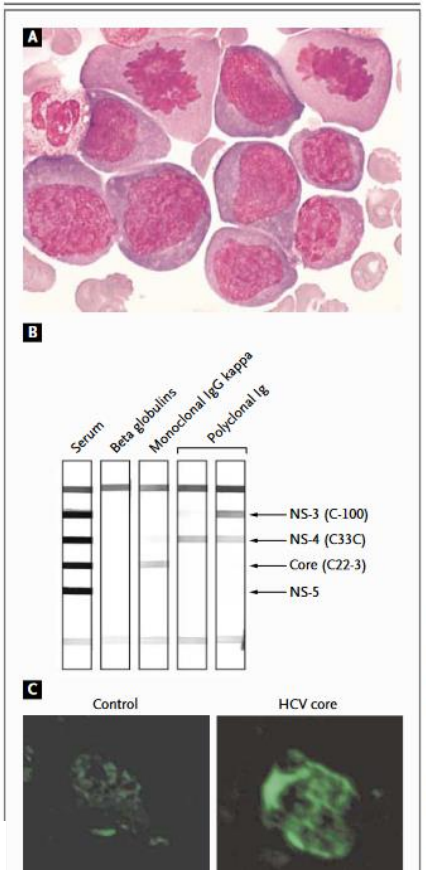

Figure 1. Studies in a Patient with Plasma-Cell Leukemia.

Panel A shows May–Grunwald–Giemsa staining of blood plasmablasts (×100). Abnormal cells exhibited a plasmablastic morphology: a large nucleus with an irregular shape; fine, homogeneous chromatin and prominent nuclei; reduced cytoplasm with little or no perinuclear hof. Mitotic figures were frequent. Panel B shows the specificity of monoclonal IgG kappa for the hepatitis C virus (HCV) core protein. The patient's serum monoclonal IgG kappa was separated by charge from polyclonal immunoglobulin (Ig) and beta globulins on an agarose gel (Paragon SPE-II, Beckman Coulter). Parts of the gel corresponding to each protein fraction were carefully cut, and proteins were eluted. The purity of each protein fraction was confirmed by immunofixation analysis (Titan Immunogel, Helena Biosciences), and then purified immunoglobulin was subjected to a recombinant immunoblot assay (RIBA III, Ortho Diagnostic Systems), which detects immunoglobulin directed against fragments of the HCV nonstructural proteins NS-3, NS-4, and NS-5 and fragment C22-3 of the core protein. Two purified polyclonal immunoglobulin fractions recognized HCV NS-3 and NS-4 proteins. The monoclonal IgG kappa fraction recognized HCV core protein; it also weakly recognized NS-4, most likely because of overlap with one polyclonal immunoglobulin fraction. The beta globulin fraction, used as a negative control, did not recognize HCV peptides. Panels C and D show immunofluorescence studies. Plasmablasts were incubated with a primary antibody — a control antibody or an antibody specific for HCV core protein (Affinity Bioreagents) or specific for the human herpesvirus 8 (HHV-8) productive phase ORF 59 or ORF K8.1 (Advanced Biotechnologies) — and then with a secondary antibody labeled with fluorescein isothiocyanate. Images show the perinuclear, globular fluorescence characteristic of HCV. Magnification was ×100 for HCV and ×40 for HHV-8.

60% of Mc Ig from HBV-infected Patients Recognize a HBV protein

Targets of the Mc Igs of 18 HBV-infected patients with MGUS (n=6) or MM (n=12)

- MIAA assay + confirmation by dot blots
- GlcSph assay

Identified Targets

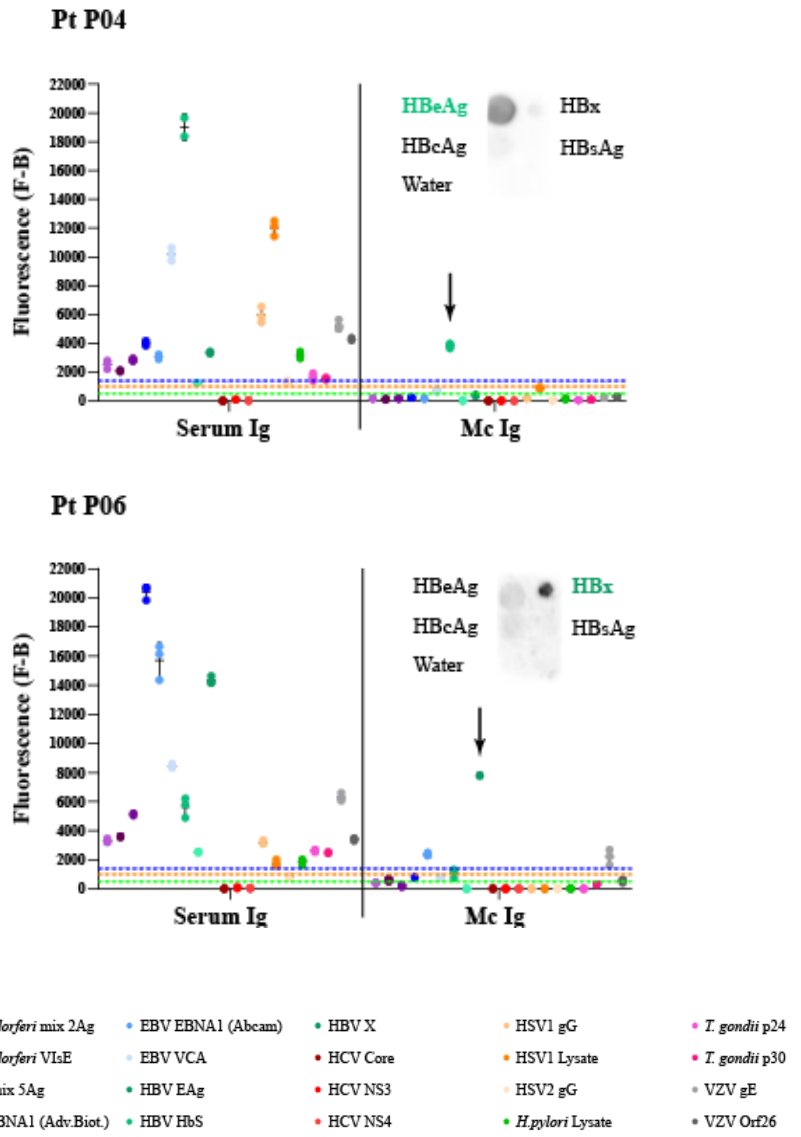
- **HBV (n=11)** 4 MGUS, 7 MM
- **EBV (n=3)** 2 MGUS, 1 MM
- **HSV-1 (n=2)** 2 MM
- ***H. pylori* (n=1)** 1 MM
- **GlcSph (n=1)** 1 MM

HBV

Target of **61%** HBV-infected MGUS/MM patients

Target proteins:

HBV X protein (n=7), HBeAg (n=2), HBc (n=2)



Efficacy of Target Antigen Reducing Therapy: HBV

Efficacy of anti-HBV and anti-HCV treatments in MM patients - Collaboration

		Patients in cohort	Patients with outcome	Survival probability at the end of time window
HBV cohort	Global MM post HBV infection with AVT	175	36	77.91 %
	Global MM post HBV infection no AVT	1192	329	68.41 %
	Log-Rank Test	χ^2 5.786	df 1	p 0.016
HCV cohort	Global MM post HCV infection with AVT	179	33	80.46 %
	Global MM post HCV infection no AVT	1041	253	70.78 %
	Log-Rank Test	χ^2 8.026	df 1	p 0.005

Anti-viral therapy significantly improves the overall survival at 3 years of MM patients infected with HBV or HCV.

Rodriguez-Garcia et al. Haematologica (2023)

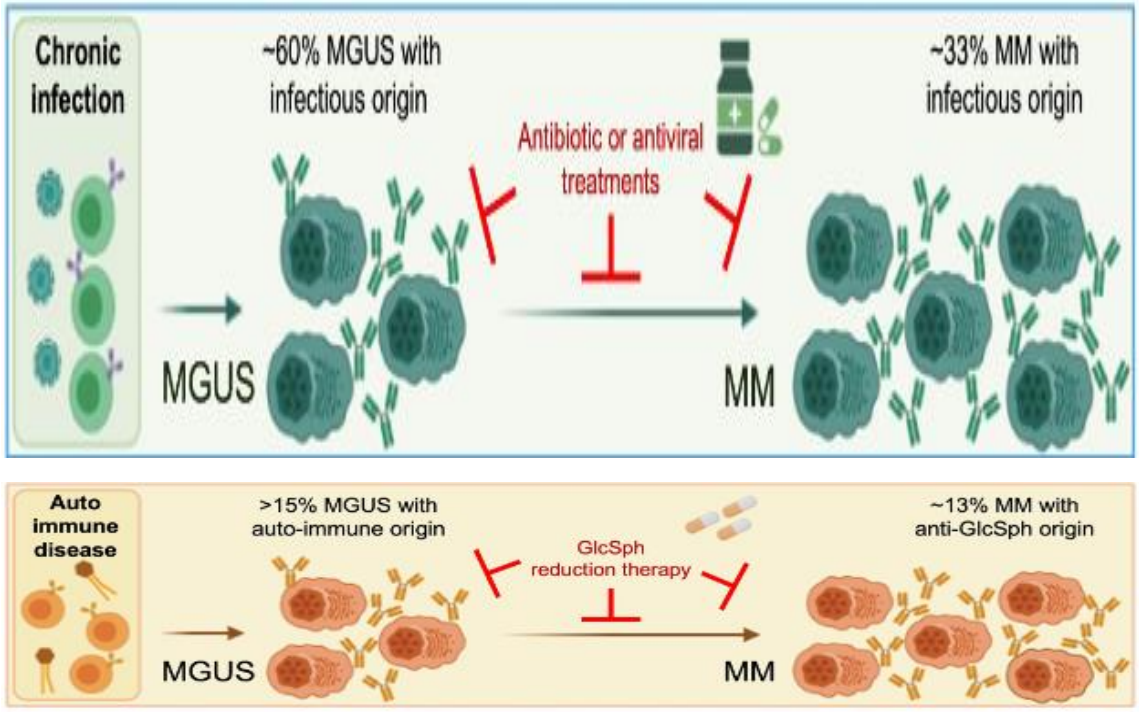
CONCLUSION (I)

- **Thanks to the MIAA assay (+ the GlcSph assay), it is now possible to determine the target of Mc Igs from the majority of patients diagnosed with MGUS, SMM or MM**

- **Knowing the target of a patient's Mc Ig is useful in terms of prognosis and therapy**

- **Target-reducing therapy is beneficial to MGUS patients (prevention of MM) and to MM patients (improved response to MM treatments)**

CONCLUSION (II)



The efficacy of target-reducing therapy is demonstrated for:

- ✓ **GlcSph** (MGUS, SMM)
- ✓ **HCV** (MGUS, MM)
- ✓ **HBV** (MGUS, MM)

- ✓ *H. pylori* (SMM): on-going studies
